ABSTRACT

Analysis of gene function in primary vascular cells has been particularly limited by low transfection efficiencies. Using internal ribosomal entry site (IRES)-based retroviral vectors, we demonstrate efficient infection (range of 45%–95%) of primary human endothelial and smooth muscle cells with genes varying in size from 1.3 to 4.5 kb. Because IRES vectors are designed to allow the expression of two genes from a single mRNA, we can show excellent correlation between the expression of a reporter gene and an inserted gene of interest. Reporter gene expression allows rapid (24–48 h) and unambiguous identification of transduced cells. Additionally, reporter gene expression can be used to isolate subpopulations of cells that express distinct levels of cistron 1 genes by flow cytometry, and sorted cells maintain relative levels of gene expression over multiple passages in culture. An ideal strategy for gene expression in mammalian cells should meet several important criteria. First, stable and efficient transduction of primary, non-transformed cells should be possible to avoid the use of cell lines. The method of gene transduction should be nontoxic, and appropriate controls for expression of selectable markers should be used. Further, gene transduction and expression or selection should be rapid for use in primary cells with a limited in vitro replicative capacity. Additionally, transduced cells should be easily identified and, if necessary, isolated from polyclonal cell mixtures. Ideally, it should also be possible to vary gene expression levels to characterize gene dosage effects. Finally, analysis of gene function(s) should be possible within large polyclonal populations of transduced cells to avoid potential clonal artifacts. Recent advances in expression techniques utilizing single-transcript retroviral vectors allow many of these criteria to be fulfilled for the first time using primary vascular cells. A limited number of recent studies have shown that single-transcript retroviral constructs can be used to efficiently transduce murine endothelial and canine vascular SMCs (12,15). However, systematic characterizations of the utility of these constructs in primary human vascular cells are not available. Here we demonstrate the utility of single-transcript retroviral vectors for the study of gene function in primary human endothelial cells and SMCs.

INTRODUCTION

The characterization of gene function in vascular cells, including endothelial and smooth muscle cells (SMCs), has been limited by two major factors. First, suitable cell lines that maintain phenotypic and functional characteristics of primary vascular cells are lacking. Second, expression of exogenous genes has been difficult because of the extremely low transfection efficiency of primary vascular cells. As a result, many studies have been performed in cell lines of uncertain physiologic relevance and/or in primary vascular cells transduced at very low efficiencies.

An ideal strategy for gene expression in mammalian cells should meet several important criteria. First, stable and efficient transduction of primary, non-transformed cells should be possible to avoid the use of cell lines. The method of gene transduction should be nontoxic, and appropriate controls for expression of selectable markers should be used. Further, gene transduction and expression or selection should be rapid for use in primary cells with a limited in vitro replicative capacity. Additionally, transduced cells should be easily identified and, if necessary, isolated from polyclonal cell mixtures. Ideally, it should also be possible to vary gene expression levels to characterize gene dosage effects. Finally, analysis of gene function(s) should be possible within large polyclonal populations of transduced cells to avoid potential clonal artifacts. Recent advances in expression techniques utilizing single-transcript retroviral vectors allow many of these criteria to be fulfilled for the first time using primary vascular cells. A limited number of recent studies have shown that single-transcript retroviral constructs can be used to efficiently transduce murine endothelial and canine vascular SMCs (12,15). However, systematic characterizations of the utility of these constructs in primary human vascular cells are not available. Here we demonstrate the utility of single-transcript retroviral vectors for the study of gene function in primary human endothelial cells and SMCs.

MATERIALS AND METHODS

Cell Culture and Reagents

Human umbilical vein endothelial cells (HUVECs) were isolated and cultured in RPMI 1640, supplemented with 15% FCS, 0.4% bovine pituitary brain extract (Invitrogen, Carlsbad, CA, USA), and 50 µg/mL heparin as previously described (4). Human arterial SMCs were derived from the media of normal thoracic aortas by explant and were maintained in DMEM supplemented with 10% FCS. We used the following antibodies: anti-HA (clone HA.11; Babco, Richmond, CA, USA), anti-E-selectin (Clone 68-5H11; BD Pharmingen, San Diego, CA, USA), phycoerythrin (PE)-labeled anti-ICAM-1 (clone HA58; BD Pharmingen), and PE-labeled goat anti-mouse IgG (Biomeda, Foster City, CA, USA).

Protein Analysis

For immunoblotting, cells were lysed in 50 mM Tris-HCl, pH 7.4, 250...
mM NaCl, 0.5% Nonide® P-40, 10% glycerol, 5 mM EDTA, 50 mM NaF, 0.5 mM Na3VO4, 10 mM β-glycerophosphate, PMSF, 5 µg/mL leupeptin and aprotinin. Lysates were separated on 10% or 15% SDS-PAGE, and proteins were transferred to Immobilon membranes (Millipore, Bedford, MA, USA) and immunoblotted with specific antibodies. Immunoblots were visualized by enhanced chemiluminescence (Amersham Biosciences, Piscataway, NJ, USA).

**Generation of Retroviral Vectors, Retrovirus Production, and Infection of Endothelial Cells and SMCs**

All retroviral expression plasmids were constructed using the pBMN-IRES-EGFP, pBMN-IRES-Lyt2a, and pBMN-IRES-PURO retroviral vectors and standard molecular biology techniques (8,9). The pBMN-IRES retroviral vectors contain a single-transcript expression cassette in which a retroviral promoter drives the expression of two genes. The pBMN-IRES-EGFP vector utilizes enhanced GFP (EGFP) as a second cistron reporter gene, pBMN-IRES-Lyt2a, a splice variant of murine CD8, and pBMN-IRES-PURO, the puromycin resistance gene. The cDNAs of human pro-HB-EGF, human MDC15, and human telomerase (hTERT) were cloned into the BamHI/NotI sites of pBMN-IRES-EGFP and IκBα-Ser into pBMN-IRES-Lyt2a. EGFP was cloned into the BamHI/NotI sites of pBMN-IRES-PURO.

Amphotrophic retrovirus was prepared with the use of Phoenix-A packaging cells as previously described (9). After transfection of Phoenix-A packaging cells, the medium was changed at 10 h and again at 24 h after transfection. Virus collected between 24 and 48 h after transfection was used for infection. Retroviral titers between 106 and 107 cfu/mL were determined by limiting dilution with NIH3T3 cells. For infection, 4 × 105 HUVECs or SMCs were plated in 25-cm² flasks 24 h before infection in normal growth medium to obtain exponentially growing cultures. The medium was replaced with 4 mL retroviral supernatant (approximate MOI 2.5–25 cfu/cell) supplemented with 4 µg/mL polybrene.

After 12 h, retroviral supernatants were removed and replaced with fresh normal growth medium for 48 h. In these conditions, no apparent toxicity was observed after a 12-h exposure to retroviral supernatants containing polybrene in either HUVECs or SMCs.

**Flow Cytometry**

For the analysis of EGFP expression after retroviral infection, cells were harvested by brief trypsinization, washed in PBS, and fixed with 2% paraformaldehyde. The percentage of EGFP(+) cells was determined by flow cytometry by the use of a FACScan flow cytometer and analyzed with BD CellQuest™ (both from BD Biosciences, San Jose, CA, USA). For two-color analysis of cells expressing the CD8 (Lyt2) retroviral cell surface marker and an EGFP reporter gene, cells were stained with a PE-conjugated anti-CD8 antibody (BD Pharmingen) for 30 min on ice, followed by three washes in PBS + 0.25% BSA and post-fixed with 2% paraformaldehyde before analysis. Similarly, expression of adhesion molecules (E-selectin and ICAM-1) or hemagglutinin (HA)-tagged HB-EGF was determined by staining with biotinylated antibodies. Immunoblots were visualized by enhanced chemiluminescence (Amersham Biosciences, Piscataway, NJ, USA).

For the analysis of EGFP expression after retroviral infection, cells were harvested by brief trypsinization, washed in PBS, and fixed with 2% paraformaldehyde. The percentage of EGFP(+) cells was determined by flow cytometric analysis of EGFP expression (Figure 1B). Similar results are seen using a specific antibody against a truncated cell-surface murine CD8 reporter gene in IRES-CD8-infected cells (not shown).

IRES-based retroviral vectors provide an effective strategy for delivering genes of varying sizes to primary vascular cells at high efficiency. We find that inclusion of a gene into the first cistron generally leads to decreased infection efficiencies with an inverse relationship between the size of the cDNA and the efficiency of retroviral infection (Figure 1B). However, infection efficiencies with a large 4.5-kb first cistron cDNA (hTERT) were still 56% and 45% for HUVECs and SMCs, respectively. Retroviral infection can also be used to simultaneously express two genes in primary vascular cells. Sequential infection of HUVECs with IRES-EGFP retrovirus followed by an IRES-CD8 retrovirus yields approximately 63% EGFP(+)/CD8(+) cells by flow cytometry (Figure 1C). Alternatively, simultaneous co-infection with a 50:50 mixture of IRES-EGFP and IRES-CD8 retrovirus yields approximately 40% EGFP(+)/CD8(+) cells (Figure 1C). Sequential and simultaneous infection of SMCs is also possible and yields approximately 20% and 11% EGFP(+)/CD8(+) cells, respectively (Figure 1C). This approach is particularly useful in characterizing gene-gene interactions, such as the effect of overexpression of a wild-type versus a dominant negative mutant within a single polyclonal population of primary vascular cells.

Stable integration of IRES-based retroviral cassettes into the host cell genome allows for the isolation of purified populations of infected cells expressing different levels of reporter genes (therefore, cistron 1 genes) by flow cytometry. The metalloprotease-disintegrin protein 15 (MDC15) is a 120-kDa cell-surface protein, encoded by a 2.5-kb cDNA, which is expressed by endothelial cells and SMCs in vitro.
and up-regulated within lesions of atherosclerosis in vivo (4). We asked whether EGFP reporter gene expression could be used to isolate distinct populations of MDC15-expressing cells and if gene expression is maintained over multiple passages in culture. Human SMCs were infected with MDC15-(HA)-IRES-EGFP virus encoding an HA epitope-tagged version of human MDC15 or control IRES-EGFP virus (Figure 2A). Polyclonal populations of cells (3 × 10^5 each) expressing low or high levels of the EGFP reporter gene were then isolated by flow cytometry. Immediate post-sort analysis confirmed the isolation of distinct populations of cells based on EGFP expression (Figure 2A). Cells were subcultured for an additional passage and analyzed for expression of the EGFP reporter gene by flow cytometry (data not shown) and for expression of HA-tagged MDC15 by Western blot analysis (Figure 2A). Sorted human SMCs maintained their relative expression levels of EGFP, and there was excellent correlation between EGFP and MDC15 expression.

To more rigorously test whether EGFP reporter gene and relative

---

**Figure 1.** IRES-based retroviral vectors provide an effective strategy for delivering genes of varying sizes to primary cells at high efficiency. (A) General structure of STCs. Transcription is initiated by promoter sequences within the viral 5′ long terminal repeat (LTR) and terminated by polyadenylation sequences within the 3′ LTR. Translation of cistrons 1 and 2 from a single mRNA proceeds by ribosome binding to 5′ Cap and IRES sequences, respectively. (B) Retroviral infection efficiency of HUVECs and SMCs with retroviral cassettes containing varying sized cistron 1 cDNAs (0-kb no cistron 1 cDNA, 1.3-kb human pro-HB-EGF, 2.5-kb human MDC15, 4.5-kb hTERT). Retroviral infection efficiencies were determined by flow cytometry. (C) Sequential versus simultaneous co-infection of HUVECs and SMCs. For sequential infection, cells were infected at passage 2 with IRES-EGFP retrovirus and at passage 3 with IRES-CD8 virus. Simultaneous infection was achieved with a 50:50 mixture of IRES-EGFP and IRES-CD8 virus at passage 2. SMCs were infected with an identical protocol at passages 7 and 8. The percentage of EGFP(+), CD8(+), or EGFP(+)/CD8(+) cells in each population is indicated.
MDC15 expression is stable over multiple passages in culture, cell sorting experiments were repeated using NIH3T3 cells that are a uniform replicative cell population capable of extended population doublings. Low and high expressing populations of NIH3T3 cells were subsequently subcultured for 3 or 11 passages (approximately 20 and 75 population doublings, respectively) (Figure 2B). The sorted NIH3T3 cells maintained their different expression levels as determined by flow cytometry and Western blot analysis (Figure 2B). These results demonstrate that EGFP reporter gene expression can be used to isolate distinct populations of cells expressing different levels of first cistron genes by flow cytometry and that stable levels of gene expression are maintained over multiple passages in vitro.

We next wanted to characterize further the correlation between expression of a reporter gene and a transmembrane protein cloned into the first cistron of an IRES-based retroviral vector in primary vascular cells. Pro-heparin-binding epidermal growth factor (Pro-HB-EGF) is a cell-surface growth factor that plays an important role in the migration and proliferation of vascular cells (14). It has been shown previously...
that cell-surface levels of pro-HB-EGF can be monitored by analysis of a version of pro-HB-EGF containing an HA epitope tag at the N-terminus of the extracellular domain (3). HA-pro-HB-EGF was cloned into the IRES-EGFP retroviral vector and subsequently used for the infection of HUVECs, leading to the generation of distinct EGFP(-) and EGFP(+) populations by flow cytometry (Figure 2C). Coordinately, HA-HB-EGF expression was determined by the use of an antibody against the HA-epitope tag and a PE-conjugated secondary antibody. The correlation between EGFP and HA-HB-EGF expression was determined by gating on populations of cells expressing increasing levels of the EGFP reporter gene, followed by the measurement of the relative HB-EGF expression (PE mean fluorescence intensity) (Figure 2C). These results demonstrate an excellent correlation between the expression of the first cistron HA-HB-EGF and the second cistron EGFP reporter gene (Figure 2C). Moreover, the data show that expression levels achieved by retroviral transduction do not saturate the intracellular machinery responsible for the processing and cell-surface targeting of HB-EGF.

Previous studies have shown that endothelial cells can be isolated by flow cytometry and subsequently used for functional analysis (10) after co-transfection with a plasmid expressing GFP and a second plasmid expressing a gene of interest. A major limitation of this approach is that expression of the GFP reporter and the gene of interest are not linked and are transient. In addition, although primary vascular cells can be sorted and subsequently subcultured (Figure 2A and data not shown), cell sorting is expensive, time consuming, and not readily available to many laboratories. Therefore, we generated an IRES-based retroviral vector expressing the puromycin resistance gene as a selectable second cistron gene (pBM-IRES-PURO) and tested the utility of this construct in generating highly purified populations of retrovirally infected primary human endothelial cells. Puromycin selection was chosen because puromycin very rapidly kills cells (1–2 days) and is inexpensive (6). A test construct was also generated in which EGFP was cloned into the pBM-IRES-PURO vector as a first cistron gene and subsequently used to infect HUVECs at approximately 50% efficiency (Figure 2D). Infected cells were subsequently split into two populations and grown in the presence of absence of puromycin (2.5 µg/mL) for 24 h, and EGFP expression was determined by flow cytometry. Cells grown in the absence of puromycin remained approximately 50% EGFP(+), whereas those in the presence of puromycin were essentially 100% EGFP(+) after 24 h of selection (Figure 2D). An identical result is obtained with an overnight (12 h) puromycin selection (data not shown). Using this approach, we can obtain virtually 100% infected populations of primary endothelial cells within 24 h with

Figure 3. Functional correlation of blockade of endothelial adhesion molecule up-regulation with infection with IκBα mutant-IRES-CD8. (A) HUVECs were infected with control IRES-CD8 or IκBα-Ser-IRES-CD8 virus before stimulation with LPS (500 ng/mL) for 3 h (E-selectin) or 6 h (ICAM-1). CD8, E-selectin, and ICAM-1 expression was determined by flow cytometry using PE-conjugated specific antibodies. Uninfected HUVECs were used to define CD8(-) and CD8(+) gates. E-selectin and ICAM-1 expression was then determined for CD8(-) uninfected and CD8(+) cells infected with the indicated retrovirus. (B) Relative expression of E-selectin and ICAM-1 in CD8(-) uninfected cells and CD8(+) retrovirally infected cells was quantified as percent maximal mean fluorescence intensity (MFI) of the PE (FL2) channel before and after LPS stimulation. Values represent MFI of duplicate samples.
no need for cell sorting.

An additional advantage of IRES-based expression cassettes is the ability to analyze transduced cells within polyclonal mixtures of infected and uninfected cells. In response to inflammatory stimuli, such as bacterial lipopolysaccharide (LPS), HUVECs rapidly up-regulate the expression of cell surface adhesion molecules, including E-selectin and intracellular adhesion molecule-1 (ICAM-1), which mediate the transmigration of circulating leukocytes into the extravascular space (2). The up-regulation of E-selectin and ICAM-1 is dependent on the activity of the transcription factor nuclear factor-κB (NF-κB), and inhibition of NF-κB activation blocks the up-regulation of E-selectin by inflammatory stimuli (1). Additionally, activity of the NF-κB transcription factor can be blocked by overexpression of the endogenous inhibitor of NF-κB (IκB-α), which contains mutations in two serine residues that prevent its degradation (17). Therefore, we used this system to test the ability of IRES-CD8-based retroviral vectors to functionally define specific subpopulations of cells within polyclonal populations of infected endothelial cells. HUVECs were infected with either control IRES-CD8 or IκB-αSer32,36-IRES-CD8 virus encoding an endogenous NF-κB inhibitor (17). The resulting cell populations were stimulated with LPS for 3 or 6 h to monitor the expression of E-selectin and ICAM-1, respectively. In response to LPS, uninfected and CD8(-) or CD8(+) cells infected with the control IRES-CD8 virus showed a marked up-regulation of E-selectin and ICAM-1 (Figure 3, A and B). In contrast, CD8(+) cells in the population infected with the IκB-αSer32,36-IRES-CD8 virus showed a markedly reduced up-regulation of E-selectin and ICAM-1 in response to LPS (Figure 3, A and B).

The stable integration of retroviral
cassettes into the genomic DNA of target cells provides novel strategies to characterize gene function by monitoring the in vitro evolution of tissue culture populations. Changes in the percentage of EGFP(+) cells may serve as an indicator of the effects of a co-transduced first cistron gene during positive or negative selective pressures on a population of infected and uninfected cells. For example, expression of a growth inhibitory gene by a retroviral IRES-EGFP cassette will impart a selective growth disadvantage to infected EGFP(+) cells. Over multiple passages in culture, the percentage of EGFP(+) cells would be predicted to decrease at the expense of the more rapidly growing uninfected EGFP(-) cells. Alternatively, expression of a gene that imparts a selective growth advantage, such as an oncogene, would lead to an increase in the percentage of EGFP(+) cells.

To test this approach in primary vascular cells, we characterized the effect of expression of telomerase (hTERT) in human aortic SMCs. Recent studies have shown that expression of hTERT in primary human cells leads to an increased in vitro lifespan through the delay of cellular senescence (18). A cDNA encoding hTERT was cloned into the pBM-IRES-EGFP retroviral vector, and human aortic SMCs were infected with hTERT-IRES-EGFP retrovirus or control IRES-EGFP virus at early passage (Figure 4). At each passage, the percentage of EGFP(+) cells and the doubling rate of the population were determined. Infection of primary SMCs with hTERT-IRES-EGFP virus led to markedly delayed senescence (Figure 4A) and an almost complete enrichment of EGFP(+) cells as the cells grew through senescence (Figure 4B). Cells infected with control IRES-EGFP virus or uninfected cells underwent senescence after 14 passages or approximately 70 population doublings. Additionally, the percentage of EGFP(+) cells in the control IRES-EGFP-infected population remained constant through senescence (not shown). hTERT-expressing cells maintained a growth rate of 5–6 population doublings per passage for 24 passages and remained approximately 100% EGFP(+) for all passages beyond normal senescence (passage 14, not shown).

In this report, we demonstrate that IRES-based retroviral cassettes provide an efficient strategy for the expression of exogenous genes in primary human vascular cells. The excellent correlation between reporter gene expression and cistron 1 gene expression makes it possible to unambiguously identify transduced cells as early as 48 h after infection. Additionally, gene expression is stable over multiple passages in culture. Reporter gene expression can be readily used to isolate subpopulations
of cells expressing distinct levels of cistron 1 genes by cell sorting. Retroviral vectors encoding selectable genes, such as the puromycin resistance gene, can also be used to very rapidly generate purified populations of infected primary vascular cells without cell sorting. Alternatively, reporter gene expression can be used to simply identify transfected cells in populations of infected and uninfected cells by flow cytometry or fluorescence microscopy.

Expression strategies, such as those presented, should provide novel approaches for characterizing gene function in primary vascular cells. For example, we have recently shown that retroviral vectors can be used to efficiently deliver NF-κB-dependent reporter genes to primary HUVECs to characterize the ability of a co-transduced gene to activate the NF-κB pathway (11). It should also now be possible to consider expression cloning strategies utilizing IRES-based retroviral cDNA libraries in primary vascular cells, as has recently been reported for other cell types (5). Finally, modifications of existing tetracycline-inducible retroviral expression systems should allow efficient and regulated gene expression in primary vascular cells with a limited in vitro replicative capacity (16).
